Numerical Rate Equation Model for the He-Cs Charge Exchange Laser

by

John F. Seely*
Numerical Rate Equation Model for
the He-Cs Charge Exchange Laser

by
John F. Seely

Abstract

A model for the He-Cs charge exchange laser has been formulated in which the coupled photon and particle rate equations are solved numerically for the laser intensities at 584 Å and 2 μ. The photon rate equations include spontaneous and stimulated emission and photoabsorption processes. The particle rate equations include charge exchange, electron impact excitation and ionization, spontaneous and stimulated emission, photoabsorption, and all appropriate back reactions. Input parameters include initial particle densities and temperatures, shapes of the leading edges of the helium plasma and target, relative drift velocity of the plasma and target, and laser length. The laser intensities are calculated as functions of time, depth into the target, and position along the laser axis.

I. Introduction

In designing experiments for the proposed He-Cs charge exchange laser, it is useful to have a rate equation model of the system in order to establish the practicability of the laser scheme and to fix operating parameters such as initial particle densities and temperatures. Such a theoretical model may also be used to interpret experimental data.

An analytical model based on approximate particle rate equations indicates that population inversions of a few percent and linear gains higher than 1 cm⁻¹ are obtainable. In this model, the four rate equations for cesium neutrals, helium ions, helium 1 ¹S₀ state, and helium 2 ¹P₁ state are written. After comparing competing reaction rates, only terms due to the fastest collisional reactions are saved in each rate equation. Spontaneous decay is included, but not stimulated emission. The approximate rate equations are then solved analytically for the population inversion and linear gain for the helium 584-Å line. Although this simple analytical model gives useful physical insight into which collisional reactions are most important in determining the population inversion, a more sophisticated numerical calculation is needed in which the coupled photon and particle rate equations, including all appropriate radiative and collisional terms, are solved simultaneously.

II. Scope of the Numerical Model

Of primary interest is the laser intensity as a function of time and position, and the dependence of the laser output on the operating parameters of the system. The collisional and radiative reactions contributing to the rate equations are modeled in detail. Plasma instabilities, magneto-hydrodynamic plasma motion, spontaneously generated magnetic fields, and related phenomena are not taken into account in this initial calculation, but may be added in subsequent models.

We anticipate that the plasma electrons will play an important role in ionizing the cesium target atoms, a process that competes with the charge exchange reaction which fills the upper laser state.
One may minimize this effect by increasing the target density to values much greater than the plasma density, so that only a small fraction of the cesium atoms is ionized.\(^7\)

We assume that the cesium target is at rest, and that the helium plasma drifts toward the target with velocity \(v_0\). The plasma ion and electron velocity distributions are assumed to be Maxwellian with constant temperatures \(T_i\) and \(T_e\), respectively. Since the cesium temperature is much less than the drift energy \((mv_0^2/2 \sim 1 \text{ keV})\) and the plasma temperatures \((T_i \sim T_e \sim 50 \text{ eV})\), we set the cesium temperature equal to zero.

As shown in Fig. 1, we calculate particle densities and laser intensities as functions of \(x\), the penetration depth into the target, and \(z\), the position along the laser axis. Stimulated photons are assumed to be emitted in the +\(z\) direction.

We treat cesium as a two-level atom composed of the ground state and the \(6\,^2\!P_{1/2},\,3/2\) excited state. Helium is treated as a three-level atom composed of the ground state and the \(2\,^1\!S_0\) and \(2\,^1\!P_1\) excited states. We are primarily interested in the laser transitions \(2\,^1\!P_1 + 1\,^1\!S_0\) at 584 Å and \(2\,^1\!P_1 + 2\,^1\!S_0\) at 2 μ.

### III. RATE COEFFICIENTS

Consider a cesium atom drifting with velocity \(\vec{v}_0\) through a helium plasma. The rate coefficient for the transfer of an electron from the cesium state \(\alpha\) to the helium state \(\beta\) is\(^5\)

\[
\alpha_{RB} = \int f_\alpha(\vec{w}) f_B(\vec{v}) |\vec{v} - \vec{w}|^2 \alpha_{QB}(\vec{v}) d^3\vec{w} \ d^3\vec{v} \tag{1}
\]

where \(\alpha_{QB}\) is the charge exchange cross section, \(\vec{w}\) is the velocity of the cesium atom, and \(\vec{v}\) is the velocity of the helium ions. Since the cesium atom has velocity \(\vec{v}_0\), the cesium velocity distribution is a delta function,

\[
f_\alpha(\vec{w}) = \delta(\vec{w} - \vec{v}_0). \tag{2}
\]

Substituting Eq. (2) into Eq. (1) and using the delta function to integrate over \(\vec{w}\), the rate coefficient becomes

\[
\alpha_{RB} = \int f_B(\vec{v}) |\vec{v} - \vec{v}_0|^2 \alpha_{QB} |\vec{v} - \vec{v}_0| \ d^3\vec{v}. \tag{3}
\]

The drift energy of the cesium atom \((mv_0^2/2 \sim 1 \text{ keV})\) is much greater than the helium ion temperature \((T_i \sim 50 \text{ eV})\). We therefore set \(|\vec{v} - \vec{v}_0| \sim v_0\) in Eq. (3), and write

\[
\alpha_{RB} = \int f_B(\vec{v}) v_0 \alpha_{QB}(v_0) \ d^3\vec{v}. \tag{4}
\]

The helium ion distribution is assumed to be Maxwellian with constant temperature \(T_i\),

\[
f_B(\vec{v}) = (m_i/2\pi T_i)^{3/2} \exp \left(-m_i v^2/2T_i\right). \tag{5}
\]

We assume that the charge exchange cross section as a function of energy \(E\) may be fitted to a curve of the form

\[
\alpha_{QB}(E) = U(E - E_c) Q_0 \ e^{-E/E_Q}. \tag{6}
\]

as shown in Fig. 2. Here \(U(x)\) is the unit step function, \(E_c\) is a threshold energy below which the cross section is zero, and \(E_Q\) is the energy at which the cross section has decreased by a factor of \(e^{-1}\). Substituting Eqs. (5) and (6) into Eq. (4) and integrating over \(v\), the rate coefficient for charge exchange becomes

\[
\alpha_{RB} = v_0 Q_0 \ e^{-E/E_Q} U(E - E_c), \ E_Q = m_i v_0^2/2. \tag{7}
\]
The cross-section parameters $Q_o$, $E_Q$, and $E_c$ entering into the rate coefficient (7) are listed in Table I. The numbering system for the atomic states $\alpha$ and $\beta$ is given by the second column in Table III. For example, the cross section for the transfer of an electron from the ground state $6^2S_{1/2}$ of cesium ($\alpha = 1$) to the $2^1P$ state of helium ($\beta = 6$) is

$$1Q_6(E) = U(E-50 \text{ eV})(2\times 10^{-15} \text{ cm}^2)\exp[-E/104 \text{ eV}].$$

The charge transfer cross-section parameters listed in Table I are taken from a theoretical calculation and should be viewed as approximate.

The rate coefficient for electron impact ionization or excitation from the cesium state $\alpha$ to the cesium state $\beta$ is

$$\alpha S^B = \int f_\alpha(\vec{w}) f_e(\vec{v}) |\vec{v} - \vec{v}_o| Q_\alpha^B (|\vec{v} - \vec{v}_o|) \, d^3v \, d^3w,$$  \hspace{1cm} (8)

where $f_\alpha(\vec{w})$ is the cesium velocity distribution and $f_e(\vec{v})$ is the plasma electron distribution. Substituting Eq. (2) into Eq. (8),

$$\alpha S^B = \int f_e(\vec{v}) |\vec{v} - \vec{v}_o| Q_\alpha^B (|\vec{v} - \vec{v}_o|) \, d^3v.$$  \hspace{1cm} (9)

We assume that the electron distribution is Maxwellian with constant temperature $T_e$, where $T_e = 50$ eV. The average velocity of the electron distribution,

$$v_{av} = (8 T_e/m_e)^{1/2},$$  \hspace{1cm} (10)

is much greater than the drift velocity. We therefore set $|\vec{v} - \vec{v}_o| \approx v$ in Eq. (9). Again assuming that the cross section may be fitted to the curve given by Eq. (6), the rate coefficient for the electron impact ionization or excitation of cesium from state $\alpha$ to state $\beta$ is

$$\alpha S^B = v_{av} Q_\alpha (1+E_c/E_c) \exp[-E_c/(1+T_e/E_c)],$$  \hspace{1cm} (11)

The rate coefficient for the electron impact ionization or excitation of helium from state $\alpha$ to state $\beta$ is

$$\alpha S^B = \int f_\alpha(\vec{w}) f_e(\vec{v}) |\vec{v} - \vec{w}| Q_\alpha^B (|\vec{v} - \vec{w}|) \, d^3v \, d^3w.$$  \hspace{1cm} (12)

Assuming a Maxwellian distribution for the electrons and using Eq. (6), the rate coefficient for the electron impact ionization or excitation of helium is the same form as Eq. (11), the result for cesium. This is because in both derivations, we have effectively assumed that the electron velocity is much greater than the ion velocity.

The cross-section parameters for electron ionization and excitation of cesium and helium are listed in Table II. Cross sections for ionization or excitation from the ground states ($\alpha = 1$ or 4) are experimental measurements. Other values are estimated using the Darwin model and should be viewed as approximate.

IV. RATE EQUATION TERMS

In this section, we develop the terms contributing to the particle rate equations due to charge exchange, electron impact ionization and excitation, and the corresponding back reactions.

The change in the number of cesium atoms of type \( \alpha \) due to the transfer of an electron to the helium state \( \beta \) may be written

\[
\frac{dn^\beta}{dt} = \left[ -n_\alpha n^\beta \left( \frac{n_6}{n^\alpha} \right) \right] \tag{14}
\]

Here \( n^\alpha \) is the number density of particles in state \( \alpha \). Using detailed balancing, the ratio of the forward and backward rate coefficients for charge exchange may be written

\[
\frac{R^\alpha}{R^\alpha} = \left( \frac{g^\beta}{g^\alpha} \right) \exp\left( \frac{-E^\beta - E^\alpha}{T_1} \right), \tag{15}
\]

where \( g^\alpha \) is the degeneracy of state \( \alpha \), \( E^\alpha \) is the energy level of state \( \alpha \), and \( E^\beta - E^\alpha \).

Values for \( g^\alpha \) and \( E^\alpha \) are given in Table IV. Substituting Eq. (15) into Eq. (14), the change in the number of cesium atoms in state \( \alpha \) due to charge exchange with helium ions is

\[
\frac{dn^\beta}{dt} = -n_\alpha n^\beta \left[ 1 - \frac{n_6}{n^\alpha} \right] \left( \frac{g^\beta}{g^\alpha} \right) \exp\left( \frac{-E^\beta - E^\alpha}{T_1} \right) \tag{16}
\]

The charge exchange rate coefficient \( R^\beta \) may be calculated using Eq. (7) and the cross-section parameters in Table I.

The change in number of atoms in state \( \alpha \) due to electron impact ionization and three-body recombination is

\[
\frac{dn^\beta}{dt} = \left[ -n_\alpha n^\beta \left( \frac{n_6}{n^\alpha} \right) \right] \tag{17}
\]

\[
= -n_\alpha n^\beta \left[ 1 - \frac{n_6}{n^\alpha} \right] \exp\left( \frac{-E^\beta - E^\alpha}{T_1} \right) \tag{18}
\]

\[
= -n_\alpha n^\beta \left( \frac{n_6}{n^\alpha} \right) \exp\left( \frac{-E^\beta - E^\alpha}{T_1} \right) \tag{19}
\]

V. PARTICLE RATE EQUATIONS

The terms included in the target rate equations are shown in Table III. These terms are:

1. Charge exchange between the cesium \( ^6S_{1/2} \) and \( ^6P \) states and the helium \( ^1S_{0}, \ 2^1S_{0}, \) and \( 2^1P_{1} \) states,

2. Electron impact ionization of the cesium \( ^6S_{1/2} \) and \( 2^P \) states,

3. Electron impact excitation \( ^6S_{1/2} \rightarrow ^6P \),

4. Spontaneous emission \( ^6P \rightarrow ^6S_{1/2} \),

5. Photoabsorption \( ^6S_{1/2} \rightarrow \) ion of 584 \( \AA \) photon, and all appropriate back reactions. The rate equations for the cesium ground state is

$\frac{\partial n_1}{\partial t} = \sum_{\beta=4,5,6} \frac{dn_{\beta}}{dt} + \frac{dn_{\beta}}{dt_{ex}} + n_2^2 A_1 - 2k_1 I_1/\hbar \nu_1$, (22)

where the fourth term is due to spontaneous decay of the $6^2P (\alpha = 2)$ state, and $2A_1$ is the transition probability given in Table V. The last term, due to photoabsorption, is derived in Section VI. The rate equation for the $6^2P$ state of cesium is

$\frac{\partial n_2}{\partial t} = \sum_{\beta=4,5,6} \frac{dn_{\beta}}{dt} + \frac{dn_{\beta}}{dt_{ex}} - n_2^2 A_1$. (23)

Adding Eqs. (22) and (23), the rate equation for cesium ions is

$\frac{\partial n_3}{\partial t} = \sum_{\alpha=1,2} \frac{dn_{\alpha}}{dt} + \sum_{\beta=4,5,6} \frac{dn_{\beta}}{dt_{ex}} + 2k_1 I_1/\hbar \nu_1$. (24)

In writing the cesium rate equations, we have assumed that the cesium atoms are at rest.

The terms included in the plasma rate equations are shown in Table III. These terms are:

(1) Charge exchange between the helium $1^1S_0, 2^1S_0$ and $2^1P_1$ states and the cesium $6^2S_{1/2}$ and $6^2P$ states,
(2) Electron impact ionization of the helium $1^1S_0, 2^1S_0$, and $2^1P_1$ states,
(3) Electron impact excitations $1^1S_0 + 2^1S_0, 1^1S_0 + 2^1P_1$, and $2^1S_0 + 2^1P_1$,
(4) Spontaneous emission $2^1P_1 + 1^1S_0$ and $2^1P_1 + 2^1S_0$,
(5) Stimulated transitions between the $2^1P_1$ and $1^1S_0$ states, and between the $2^1P_1$ and $2^1S_0$ states, and all appropriate back reactions. The rate equation for the helium ground state is

$\frac{\partial n_4}{\partial t} = \frac{\partial n_4}{\partial x} = \sum_{\alpha=1,2} \frac{dn_{\alpha}}{dt} + \frac{dn_{4}}{dt_{ex}} + \frac{dn_{6}}{dt_{ex}} + n_6^6 A_4 + g_1 I_1/\hbar \nu_1$, (25)

where the last term is due to stimulated emission from the $2^1P_1$ state to the $1^1S_0$ state at 584 Å. This term is determined as a function of the linear gain $g_1$ and the laser intensity $I_1$ in Section VI. The rate equation for the helium $2^1S_0$ is

$\frac{\partial n_5}{\partial t} = \frac{\partial n_5}{\partial x} = \sum_{\alpha=1,2} \frac{dn_{\alpha}}{dt} + \frac{dn_{5}}{dt_{ex}} + \frac{dn_{6}}{dt_{ex}} + \frac{dn_{4}}{dt_{ex}} + \frac{dn_{7}}{dt_{ex}}$, (26)
The rate equation for the helium 2 $^1p_1$ state is

$$\frac{2n_6}{\alpha} + \frac{3n_6}{\alpha} = \sum_{\alpha=1,2} \frac{6}{\alpha} \frac{dn_\alpha}{dt} + \sum_{\beta=4,5,6} \frac{7}{\beta} \frac{dn_\beta}{dt}$$

Adding Eqs. (25), (26), and (27) the rate equation for helium ions is

$$\frac{2n_7}{\alpha} + \frac{3n_7}{\alpha} = \sum_{\alpha=1,2} \frac{6}{\alpha} \frac{dn_\alpha}{dt} + \sum_{\beta=4,5,6} \frac{7}{\beta} \frac{dn_\beta}{dt}$$

Regarding the free electrons, we are primarily concerned with those electrons with sufficient energy to cause excitation or ionization events which compete with the charge exchange and laser transitions of interest. In writing the rate equation for the hot electrons, we assume that a hot electron loses an average of about 10 eV during each excitation or ionization event, and thus participates in \((T_e/10eV)\) such events:

$$\frac{2n_8}{\alpha} + \frac{3n_8}{\alpha} = \sum_{\alpha=1,2} \frac{6}{\alpha} \frac{dn_\alpha}{dt} + \sum_{\beta=4,5,6} \frac{7}{\beta} \frac{dn_\beta}{dt}$$

VI. PHOTON RATE EQUATIONS

In this section, we establish the rate equations for the laser intensities \(I_1\) and \(I_2\) of the two helium lines with wavelengths \(\lambda_1 = 584\) Å and \(\lambda_2 = 2\) μ, as shown in Table V. According to Ref. 5, the equation for the laser field strength \(E_i^2\) is

$$\frac{3}{\alpha} \frac{dn_\alpha}{dt} = c \varepsilon_i E_i^2 - 2 c k_i E_i^2$$

where \(k_i\) is the absorption coefficient and the linear gain is

$$g_i = (3/2)(4n2/\pi) \varepsilon_i (\lambda_i^2 \sigma_i n_o / \Delta E_i) \left(1 - f_i \right) c^2 b^2 \text{erfc}(b)$$

Due to the plasma ion temperature \((T_i = 50\) eV), the Doppler broadening is determined by the thermal motion of the ions:

$$\Delta\omega_i = v_i \Delta \nu/c = 2 \pi \sqrt{3} T_i^{1/2} / \lambda_i \mu_i^{1/2}$$

where \(\mu_i\) is the mass of the ion. In writing Eq. (30), we have assumed that the photons travel in the z direction, as shown in Fig. 1. Since \(E_i^2\) is proportional to the photon number density \(n_i\), Eq. (30) may be written

$$\frac{2n_i}{\alpha} + \frac{3n_i}{\alpha} = c g_i n_i - 2 c k_i n_i + n_o \sigma A_i F_i$$

Here \(n_o\) is the plasma density, \(f_i\) is the fraction of helium atoms in the upper laser state \(\alpha\), \(f_\beta\) is the fraction in the lower state \(\beta\), \(\Delta E_i\) is the Doppler broadening, and

$$b = \sqrt{\omega i} \sigma A_i / \Delta E_i$$
where the last term is due to the spontaneous decay of the upper state \( a \). Here \( F \) is the fraction of spontaneous photons which passes through the region of positive population inversion. Using \( n_i = I_i / \nu_i c \), where \( I_i \) is the laser intensity and \( \nu_i = 2 \pi c / \lambda_i \), the gain term in Eq. (34) may be written \( g_i I_i / \nu_i \). This is the stimulated emission term used in the helium atom rate equations (25) - (27). From Eq. (34), the equation for the laser intensity \( I_i \) is

\[
\frac{\partial I_i}{\partial t} + c \frac{\partial I_i}{\partial z} = c g_i I_i - 2 c k_i I_i + \hbar \nu_i c n_a \sigma A F. \quad (35)
\]

The two photon rate equations represented by Eq.(35), where \( i = 1 \) and \( 2 \), and the eight particle rate equations (22) - (29) form a system of ten coupled equations which may be solved for the ten unknowns.

\[ n_\alpha, \text{ where } \alpha = 1, 2, \ldots, 8 \]

and

\[ I_i, \text{ where } i = 1, 2. \]

VII. INITIAL AND BOUNDARY CONDITIONS

The cesium target is taken to be at rest, and the helium plasma approaches the target with velocity \( V_0 \) as shown in Fig. 1. At the leading edges of the cesium target and the plasma, the particle densities increase from zero to \( 10^{16} - 10^{19} \text{ cm}^{-3} \). We assume that the rise in cesium density is \( [1-\exp(-x/x_{cs})] \), where \( x_{cs} \) is a scale length. The plasma density profile is of the same form with scale length \( x_{He} \). The initial density profile of the target is shown in Fig. 3(a), where \( n_\alpha^{\text{initial}} \) is the initial particle density in the interior of the target. Since the plasma is traveling toward the target, the rise in density of the plasma represents a boundary condition at the leading edge of the target. The rise in density of the plasma at \( x = 0 \) is shown in Fig. 3(b), where \( t_{He} = x_{He} / V_0 \).

We also simulate a ragged leading edge for the target as shown in Fig. 3(c), where the coordinate axes are oriented as in Fig. 1. Here \( \ell \) is the number of lobes at the leading edge, and \( x_{\text{rag}} \) is the depth of the lobes. The target density is zero in the lobes, and then increases from the curve

\[ x = x_{\text{rag}} \sin^2 \left( \frac{2\pi x}{z_{\text{max}}} \right), \quad (36) \]

where \( z_{\text{max}} \) is the laser length. We assume that the plasma leading edge is uniform along the \( z \) direction with no ragged edge effects.

\[ \text{Fig. 3} \]

VIII. RATE EQUATIONS IN DIMENSIONLESS FORM

We define the dimensionless particle density

\[ D_\alpha = n_\alpha / n_0, \quad (37) \]

where \( n_0 \) is the initial plasma density. The dimensionless penetration depth is

\[ X = x_{\text{rag}} 6_A^4 / V_0, \quad (38) \]

where \( 6_A^4 \) is the transition probability of the 584-A helium line given in Table V, and \( V_0 \) is the drift velocity. If \( V_0 = 2.2 \times 10^7 \text{ cm/s} \), which corresponds to drift energy \( 1/2 m V_0^2 = 1 \text{ keV} \), then the scale length \( V_0 / 6_A^4 \) is 0.12 \( \text{mm} \). We define the dimensionless time

\[ T = 6_A^4 t \quad (39) \]

and the dimensionless position along the laser axis
with scale length $c/\lambda_4$ equal to 16.7 cm. From Eq. (16), the dimensionless charge exchange term is written
\[
cx(\alpha, \beta) = D_\beta D_\alpha \alpha^\beta \left[ 1 - \left( \frac{D_\beta D_\alpha}{D_\alpha D_\beta} \right) \left( g_\beta / g_\alpha \right) \exp \left( E_\beta - \alpha / T_e \right) \right],
\]
where the charge exchange rate parameter is
\[
\alpha^\beta = n_o A_a^\beta / \lambda_4,
\]
and $A_a^\beta$ is given by Eq. (7). From Eq. (19), the dimensionless electron impact ionization term is
\[
\text{EION}(\alpha, \beta) = D_\beta D_\alpha \alpha^\beta \left[ 1 - \left( \frac{D_\beta D_\alpha}{D_\alpha D_\beta} \right) \left( h^2 / 2m_e \right)^{3/2} \right] \exp \left( \frac{E_\alpha - \alpha / T_e}{2} \right),
\]
where the impact ionization rate parameter is
\[
\alpha^\beta = n_o A_i^\beta / \lambda_4
\]
and $A_i^\beta$ is given by Eq. (11). From Eq. (20), the electron impact excitation rate term is written
\[
\text{EXCITE}(\alpha, \beta) = D_\beta D_\alpha \alpha^\beta \left[ 1 - \left( \frac{D_\beta D_\alpha}{D_\alpha D_\beta} \right) \left( g_\beta / g_\alpha \right) \exp \left( E_\alpha - \beta / T_e \right) \right].
\]
We define the dimensionless laser intensity
\[
B_1 = I_1 / h \nu_1 c n_o,
\]
where $\nu_1 = 2\pi c / \lambda_1$ and $\lambda_1 = 584$ Å as given in Table V. The scale intensity $h \nu_1 c n_o$ corresponds to photons with energy $h \nu_1$ and number density $n_o$ traveling with speed $c$. For plasma density $n_o = 10^{16}$ cm$^{-3}$, the scale intensity is $10^9$ W/cm$^2$. The dimensionless gain is
\[
G_1 = c \ g_1 / \lambda_4,
\]
where the scale gain is $\lambda_4 / c = 0.06$ cm$^{-1}$ and $g_1$ is given by Eq. (31). The dimensionless stimulated emission term which appears in the particle rate equation is
\[
\text{STIM}(1) = \lambda_1 \ G_1 B_1 / \lambda_1,
\]
and the dimensionless spontaneous emission term is
\[
\text{SPONT}(1) = D_\alpha \ A_\alpha / \lambda_4.
\]
We also define the dimensionless photoabsorption term
\[
\text{PHOTO}(1) = 2k_1 c \lambda_1 / \lambda_1^6 \lambda_4.
\]
Using the dimensionless quantities defined above, the particle rate equations (22)-(29) may be written in the dimensionless form
\[
\frac{\partial}{\partial \tau} = - \frac{\partial}{\partial \lambda} \text{CX}(1,8) - \text{EION}(1,3) - \text{EXCITE}(1,2) + \text{SPONT}(3) - \text{PHOTO}(1) \times B_1,
\]
\[
\frac{\partial}{\partial \lambda} \text{CX}(1,2) - \text{EION}(2,3) + \text{EXCITE}(1,2) - \sum_{\lambda'=4,5,6} \text{SPONT}(2) - \text{STIM}(1)
\]
\[
\frac{\partial}{\partial \lambda} \text{CX}(2,5) - \text{EION}(5,7) + \text{EXCITE}(4,5) + \text{SPONT}(2) + \text{STIM}(2)
\]
\[
\frac{\partial}{\partial \lambda} \text{CX}(3,6) - \text{EION}(6,7) - \sum_{\lambda'=4,5,6} \text{EXCITE}(4,5) - \text{SPONT}(3) - \text{STIM}(3),
\]
\[
\frac{\partial}{\partial \lambda} \text{CX}(4,7) - \text{EION}(7,8) - \sum_{\lambda'=4,5} \text{EXCITE}(1,2) - \text{EXCITE}(4,5) - \sum_{\lambda'=4,5} \text{EXCITE}(\lambda',6)
\]
\[
\frac{\partial}{\partial \lambda} \text{CX}(5,8) - \text{EION}(8,7) - \sum_{\lambda'=4,5} \text{EXCITE}(\lambda',7) + \sum_{\lambda'=4,5,6} \text{EION}(\lambda',8) - \text{EXCITE}(1,2) - \text{EXCITE}(4,5) - \sum_{\lambda'=4,5} \text{EXCITE}(\alpha,6) / \text{NIMP},
\]
where $\text{NIMP} = T_e / 10$ ev is the number of events in which each hot electron participates. The photon rate equation (35) may be written in the dimensionless form
\[
\frac{\partial}{\partial \lambda} \text{PHOTO}(3) - \frac{\partial}{\partial \lambda} \text{PHOTO}(1) \times G_1 \ = \ G_1 B_1 - \text{PHOTO}(1) \times B_1 + \text{PHOTO}(1) \times B_1 / \lambda_4\text{SPONT}(1) / \lambda_1.
\]
Equations (50) - (58) are the ten equations to be solved numerically.
To permit use by others, the computer code is described. A simplified flow diagram for the main program is shown in Fig. 4.

The input parameters are punched on three data cards. The first data card contains values for the following FORTRAN variables:
- \( \text{DELT} \) = time interval
- \( \text{DELI} \) = penetration depth interval
- \( \text{DELZ} \) = laser axis interval
- \( \text{TMAX} \) = maximum value of time
- \( \text{XMAX} \) = maximum penetration depth
- \( \text{ZMAX} \) = laser length
- \( \text{NUMT} \) = number of times calculated results are printed

Variables on the second data card determine the initial and boundary conditions:
- \( \text{DI}(1) \) = initial density of the cesium ground state \( 6^2S_{1/2} \)
- \( \text{DI}(2) \) = initial density of the cesium \( 6^2P \) state
- \( \text{DI}(3) \) = initial density of cesium ions
- \( \text{DI}(4) \) = initial density of the helium ground state \( 1^S_0 \)
- \( \text{DI}(5) \) = initial density of the helium \( 2^1S_0 \) state
- \( \text{DI}(6) \) = initial density of the helium \( 2^1P_0 \) state
- \( \text{DI}(7) \) = initial density of helium ions
- \( \text{DI}(8) \) = initial density of plasma electrons
- \( \text{XCS} \) = cesium density scale length
- \( \text{XHE} \) = plasma density scale length
- \( \text{XRAG} \) = depth of lobes on the target edge
- \( \text{LOBE} \) = number of lobes on the target edge.

These FORTRAN variables correspond to the initial and boundary condition variables shown in Fig. 3. For example, \( \text{DI}(1) = n_{\text{initial}} / n_0 \) and \( \text{XRAG} = x_{\text{rag}} \).

Values for the following FORTRAN variables are contained on the third data card:
- \( \text{TEMPE} \) = plasma electron temperature in eV\( (T_e) \)
- \( \text{TEMPI} \) = plasma ion temperature in eV\( (T_i) \)
- \( \text{DZERO} \) = plasma density in cm\(^{-3}\) \( (n_o) \).

After reading and printing the input parameters contained on the three data cards, the main program calls SUBROUTINE INITIAL. This subroutine assigns the initial values to the eight particle densities \( \text{D(NUM)} \), where \( \text{NUM} = 1, 2, \ldots, 8 \). The initial values of the gains \( \text{G(1)} \) and \( \text{G(2)} \) and the laser intensities \( \text{B(1)} \) and \( \text{B(2)} \) are set equal to zero. Here \( I = 1 \) is the \( 584-A \) line, and \( I = 2 \) is the \( 2 \mu \) line.

The main program next calls SUBROUTINE PRINT. This subroutine prints the time \( T \), as shown in Fig. 5, and then the position along the laser axis from \( Z = 0 \) to \( Z = Z\text{MAX} \). The penetration depth \( X \), from \( X = 0 \) to \( X = X\text{MAX} \), is printed along the left edge of the paper. The particle densities \( \text{D(NUM)} \), gains \( \text{G(1)} \) and \( \text{G(2)} \), and laser intensities \( \text{B(1)} \) and \( \text{B(2)} \) are printed as functions of \( X \) and \( Z \).
The plasma densities \( D(l, 2, 3) \) are assigned in SUBROUTINE BOUND. The main program then calls SUBROUTINE TARGET in which the cesium densities \( D(l) \) are calculated using Eqs. (50) - (52). This subroutine calls on FUNCTION EXCITE \((N, M)\), FUNCTION EION \((N, M)\), and FUNCTION SPONT \((I)\) for the various rate equation terms. The charge exchange and electron impact excitation and ionization rate parameters are calculated in FUNCTION RHON \((N, M)\) and FUNCTION SIG \((N, M)\), according to Eqs. (42) and (44). The plasma particle densities \( D(N,M) \), where \( N = 4, 5, 6, 7, \) and \( 8 \) are calculated in SUBROUTINE PLASMA using Eqs. (53) - (57). Population inversions are found from the particle densities, and the gains for the 584-\( \AA \) and 2 \( \mu \) lines are calculated in SUBROUTINE GAIN using Eqs. (47) and (31). The intensities of the 584-\( \AA \) and 2 \( \mu \) radiation are calculated in SUBROUTINE INTENS according to Eq. (58). The calculated values are printed as shown in Fig. 5. The time is advanced by DELT, and new values are calculated and printed until \( T = T_{\text{MAX}} \) is reached. Depending on the choice of step sizes, the program requires several minutes of CPU time on the CDC 7600 computer.

**X. NUMERICAL RESULTS**

In this section we discuss the numerical solution of Equations (50)-(58) for the set of operating parameters given in Table VI. The large cesium target density \( n_{\text{Cs}} = 10^{19} \text{ cm}^{-3} \) may be produced by vaporization from a flash-heated wire or plate. Since the target density is much greater than the plasma density \( n_{o} \), the effects of electron impact ionization and excitation of the cesium atoms, reactions that compete with the charge exchange process which populates the upper laser level, are minimized.

![Fig. 5](image_url)

That is, only a small fraction of the cesium ground state density is lost due to electron impact events.

<td>( 2.2 \times 10^{7} \text{ cm/s} )</td>
</tr>
</tbody>
</table>

When the plasma intersects the target, charge exchange occurs in the interaction region and the upper laser state is populated. As the excited helium atoms drift deeper into the target, spontaneous and stimulated emission occur which fill the ground state of the helium atoms. Thus, a positive population inversion occurs near the edge of the target, and decreases with depth into the target. The depth at which the population inversion is a maximum is \( x = 0.8 \) (\( x = 0.1 \text{ mm} \)) for the operating parameters listed in Table VI. The gain for the 584-\( \AA \) line is in basic agreement with the analytical theory for early time \((T \lesssim 4)\) when the stimulated emission and laser intensity are small. The gain is uniform along the laser axis, and the intensity increases nearly exponentially with \( Z \) as shown in Fig. 6. By time \( T = 8 \) (\( t = 4.5 \text{ ns} \)), saturation effects begin to limit the laser intensity. The maximum intensity of 584-\( \AA \) radiation is of order \( 10^{6} \text{ W/cm}^{2} \).
The operating parameters have been varied about the typical values listed in Table VI with the following results:

1. When the cesium density is increased to $10^{20}$ cm$^{-3}$, the laser intensity grows more rapidly as a function of time due to the increased charge exchange rate term [c.f. Eq. (14)]. Saturation effects occur at an earlier time ($T = 6$), and the maximum intensity remains of order $10^6$ W/cm$^2$. Due to the increased target density, rapid charge exchange, and thus the maximum population inversion, occur closer to the target edge ($x < 0.04$ mm). When the cesium density is reduced to the plasma density ($n_{Cs} = n_o = 10^{16}$ cm$^{-3}$), electron impact events destroy the cesium ground state population on a time-scale short compared to the spontaneous lifetime. That is, the population inversion is positive only for times $T < 1$, and the radiation intensity is not significantly greater than the spontaneous background.

2. When the drift velocity $v_o$ is increased by a factor of 2, the intensity grows more rapidly as a function of time due to the increased charge exchange rate coefficient [c.f. Eq. (7)]. Since the faster moving helium atoms travel deeper into the target before undergoing spontaneous decay, the maximum population inversion occurs at a greater depth. The maximum laser output remains of order $10^6$ W/cm$^2$. The charge-exchange cross section decreases when the drift energy is greater than $E_{O/2} (= 5$ keV from Table 1). Although a computer run has not been made for this range of drift velocity, it seems reasonable to expect that the maximum laser intensity would be reduced.

3. The maximum laser intensity is roughly proportional to the plasma density $n_o$. That is, the intensity is of order $10^7$ W/cm$^2$ for plasma density $10^{17}$ cm$^{-3}$.

4. When the plasma temperatures are varied by 20 eV, the maximum laser intensity varies by less than an order of magnitude.

5. A reduction in the density scale lengths $x_{Cs}$ and $X_{He}$ results in an increase in the intensity growth rate. This is because the cesium and helium densities build up more rapidly in the interaction region. The depth at which the population inversion is a maximum is closer to the target edge.

ACKNOWLEDGMENTS

Thanks are expressed to J. E. Brolley and C. D. Cantrell for the hospitality of L-Division, where most of the numerical work was done, and to J. Accetta for computing assistance. We also acknowledge the work of M. O. Scully, who contributed to the formulation of the rate equations and to the interpretation of the numerical results. We have benefited from enthusiastic discussions with F. Hopf, P. Meystre, D. Anderson, and J. McCullen.
